Simulation of Roulette Method

Simulation Results and Performance Metrics

For the course: “Electrical Measurements and Instrumentation (ECE_621)”

ECE - University of Patras – 2026

By Giorgos Georgiopoulos – AM:1085159

Academic email: up1085159@ac.upatras.gr

This project was developed using Python, where the simulation algorithm and the generation of graphs were created. The resulting data tables were stored using Microsoft Excel. Both the source code, the generated figures and data files alongside this report and can be found in the project repository on my GitHub at the following link: https://github.com/Georageo .

Introduction

Queueing systems are an important area of study in the analysis of networks, computer systems, and, generally, in systems where multiple requests compete for a limited number of service resources. Understanding the behaviour of such systems is essential for evaluating their performance, estimating the probability of losses, and determining the appropriate number of resources required to provide services that satisfy our goal.

In this project, the operation of such a system is studied through simulation using the roulette method, which is based on the theory of Markov chains. This method allows the simulation of the system's states to progress by using random numbers that follow a uniform distribution. In this way, it is possible to study the behaviour of the system and estimate important performance measures, such as the probability of call loss.

To generate the random numbers, the multiplicative congruential method is used, which is a technique for producing pseudo-random numbers in computational simulations. These numbers are then used in the roulette method to simulate the transitions between the states of the system.

The System

The system used in this project is a service system of type M/M/3, according to Kendall's notation. This type of system consists of three servers that provide service to incoming requests (calls). The system operates without a waiting queue, which means that if all servers are busy when a new call arrives, the call cannot be served and is immediately rejected (lost).

The state of the system is defined by the variable **n**, which represents the number of active calls being serviced at the moment. The possible states range from 0 to 3, corresponding to the number of servers that are occupied with calls. When a call arrives and a server is free (n < 3), the system transitions from state n to state n + 1. When a service is completed, the system transitions from state n to n − 1. However, if a call arrives when the system is already in state n = 3, the call is blocked and lost, while the system remains in the same state.

- The offered traffic load in the system is 2.2 Erlang (a=2.2), which represents the average traffic caused by the incoming calls.
- The probability of the arrival of a call / request is $P_a = \frac{a}{a+n}$.
- The probability of the departure of a call / request is $P_b = \frac{n}{a+n} = 1 - P_a$.

If Y is the pseudo-random number from the uniform contribution, then:

- A call arrives ,if $0 < Y < P_a$ and the state progresses to n+1
- A call departs, if $P_a < Y < 1$ and the state progresses to n-1
- A call is lost, if all servers are occupied (n=3) and the state does not progress.

Pseudo-random Number Generation

In order to perform the simulation, a sequence of pseudorandom numbers is generated using the multiplicative congruential method:

$$x_n = k\, x_{n-1}\ (mod M)$$

where x_n is the current number, x_{n-1} the previous number, k is a constant, and M is the modulus. The first value of the algorithm, x_0, is the seed number and determines the starting point

A key property of such generators is the period, which is the number of generated values before the algorithm begins to repeat. To ensure a satisfactory long period, specific conditions must be in place. When the modulus is chosen as $M = 2^b$, the maximum possible period of the generator is 2^{b-2} (provided that the multiplier satisfies the condition $k = \pm 3 (mod 8)$ and the seed number is an odd prime number > 1.

In our case, the goal is to generate a sequence of 32 pseudorandom numbers with the maximum possible period using the multiplicative congruential generator. So, $2^{b-2} = 32$, which gives b=7. So, the modulus is $M = 2^7 = 128$. For k, we choose 3 for convenience. The initial seed number for the first simulation will be 19 (AM:1085159 , so $2 \times 9 + 1 = 19$, odd prime number).

Results

Briefing

The results of the simulation will be presented in a table containing all the necessary parameters and calculated values for each step of the algorithm. The table will include the generated pseudorandom numbers, the corresponding system states, and the resulting events (arrival, departure, or call loss). The trunks correspond to the availability vector of the servers, for example, if all servers are occupied, the vector is (1 1 1), and if all servers are available, the vector is (0 0 0).

In addition, a graphical representation of the results will be provided. The graph will illustrate the probability of call loss as a function of the seed number, including the result obtained from the current simulation as well as those from previous simulations. This comparison allows for a clearer visualization of how the estimated loss probability changes with different seed numbers and how the simulation results approach the theoretical value, which is 24%.

Conclusions

The simulation results provide an estimation of the call loss probability for an M/M/3 system with a traffic load of 2.2 Erlang. The values obtained from the simulations vary depending on the seed number used for the number generator, since each one produces a different list of random numbers and so, a different sequence of state transitions of the system. As a result, the estimated loss probability may change between simulations and may also deviate from the theoretical value given by the Erlang B formula (24%), especially because the simulation is based on a relatively small number of repetitions (32 steps). We can clearly see that in the difference between the graph of first 4 (Picture 4) and the graph of the complete simulation (Picture 8) , in which the second (0.28), third (0.28), fourth (0.2308) and last (0.2308) simulation approach the value of 0.24 with the other ones deviating a lot.
